Prior to our study, when an experiment required Varroa free colonies, we would dust bees with powder sugar as a means of removing mites. Dusting with powder sugar was also gaining popularity in the beekeeping arena as a method of controlling Varroa. In 2009, researchers in Florida conducted a study which examined the efficacy of powder sugar and found it did not help in controlling Varroa. However, even though the study was sound, powder sugar only dislodges phoretic mites and not ones inside the cell. Therefore, for powder sugar to be effective it would have to be applied during broodless periods, which Florida rarely experiences due to its warmer climate. So we decided to design an experiment that would test the efficacy of powdered sugar when applied during broodless times verses when brood was present.

Unfortunately, as the study revealed, relying solely on powdered sugar as a means of controlling Varroa mites does not keep mite populations from reaching devastating levels. This was bad news for us here at the lab. We were hoping that powdered sugar would be the cure-all, a silver bullet, that one control method that worked which didn’t include chemicals in the mix, but it’s not. Yes, it does work at dislodging mites but is not “powerful” enough to remove enough mites in order to keep them from eventually causing damage to colonies. If you are or are planning to use powder sugar, be aware that it needs to be “part of” your Varroa management scheme and not your only choice.

Below then is the paper we published showing the results of our study. It was originally published in the Journal Of Apicultural Research, an IBRA publication www.IBRA.org. We thank them for permission to reprint this important study on these pages.
non-treated controls (never treated with powdered sugar or any remedial action), raising the experiment to $n=72$ colonies. These colonies provided an additional treatment group for comparison in one-way ANOVAs against the simple effect of powdered sugar.

After colonies were established, they were managed optimally for swarm control and honey production while administering the prescribed treatments. In January prior to administering the first treatments and again in May and October, we collected the following measures of colony strength and mite numbers using published methods (Ellis et al., 2009): bee population, brood area (cm$^2$) (only in May and Oct), brood viability (72-hr survivorship of open larvae), and number of phoretic mites per 100 bees (derived from strained alcohol samples of ~300 bees). Additionally, the number of mites retrieved on three-day bottom board sticky sheets (adjusted for mite catch per 24 h) was collected for each surviving colony on 19 Jan, 8 Mar, 16 Apr, 1 Jun, 25 Jun, 30 Jul, 17 Aug, 25 Sep, and 11 Oct. All statistical analyses were done with SAS JMP (version 8.0.2).

Our first question was simply whether Varroa mite levels were affected by powdered sugar treatment. To test this, we pooled all 64 colonies in the balanced experiment into one “treated” group (irrespective of the $2^3=8$ sugar combinations described above), assigned each a random number, and sorted them by random number, thus creating eight randomly-assigned groups of eight treated colonies. Each of these treated groups thus presented a comparison group to the eight untreated control colonies, essentially letting us perform eight separate ANOVAs on the dependent variables. In two of eight ANOVAs (25%), powdered sugar significantly reduced colony mite levels. In one analysis, the number of phoretic mites per 100 bees averaged across Jan-Oct was significantly ($F=4.4; df=1,14; P=0.0537$) lower in the treated group ($3.0 \pm 0.98$ (mean ± SE), $n=8$) than the control group ($6.0 \pm 0.98$, $n=8$). In another analysis, the number of mites caught on sticky sheets per 24 h averaged across Jan-Oct was significantly ($F=4.7; df=1,14; P=0.0475$) lower in the treated group ($24.4 \pm 7.3$, $n=8$) than the control group ($46.9 \pm 7.3$, $n=8$). No other parameters of interest responded to powdered sugar in these tests.

We next turned our attention to the balanced experiment in order to tease out effects of month of treatment initiation, mode of dust application, treatment interval, and any interactions thereof. The only significant effect in a whole-model analysis was an interaction between mode of application and treatment interval for cm$^2$ brood in May. Deeming this uninteresting, we simplified the analyses by treating month of initiation, mode, and interval as simple effects in one-way ANOVAs. The number of phoretic mites per 100 bees in October was significantly ($F=4.8; df=1,22; P=0.0401$) lower in colonies in which powdered sugar treatment began the previous January ($3.4 \pm 0.9$ mites (mean ± SE), $n=11$) compared to colonies in which treatment was delayed until March ($6.1 \pm 0.8$, $n=13$). This suggests that powdered sugar dusting is more efficacious when it can be applied early and exploit a winter brood-free period. Colony bee population in May was significantly ($F=3.9; df=1,61; P=0.0524$) higher in colonies in which powdered sugar had been blown into hive entrances ($8496 \pm 710$ bees, $n=32$) compared to colonies which had received powdered sugar by sifting onto exposed brood comb top bars ($6493 \pm 721$, $n=32$). This suggests that applying powdered sugar with forced air at the hive entrance was less disruptive to bee populations than exposing and dusting comb top bars. No other parameters of interest responded to independent variables in these one-way ANOVAs.

A final observation of interest is the number of colonies surviving at the end of the experiment. Of the eight non-treated control colonies, three ($3/8=38\%$, $n=1$) were alive in October. Average survival among the eight sets of randomly-derived treated colonies was $39 \pm 6.4\%$ (mean ± SE), $n=8$.

In conclusion, powdered sugar treatment resulted in lower colony Varroa levels in two of eight (25%) separate analyses. We have evidence that powdered sugar is most efficacious when it can be applied early in the season and exploit a winter brood-free period. A labor-saving technique of applying powdered sugar dust at hive entrances with forced air appears to be less disruptive to colony bee populations than a more invasive practice of sifting sugar onto exposed brood comb top bars. In spite of these highlights, we cannot pretend that these results are a strong affirmation of powdered sugar in the fight against Varroa. The method was ineffective at reducing...
Varroa in 75% of our analyses. Moreover, 10-month colony survival between treated and non-treated colonies was virtually identical, and poor, at 38-39%. Powdered sugar is, at best, another “weak” IPM component that may contribute toward Varroa management when used in conjunction with other components.
